

Naïve Bayes Classifier

This is also a supervised learning method wherein the probability of occurrence of each test data in a particular class depends on the individual probabilities of each independent feature from the training data. Here, each feature can be assumed to be independent and thus the name naïve.

Bayes' Theorem finds the probability of an event occurring given the probability of another event that has already occurred. Bayes' theorem is stated mathematically as the following equation:

$$P(A|B) = \frac{P(B|A)P(A)}{P(B)}$$

where A and B are events and $P(B) \neq 0$.

- Basically, we are trying to find probability of event A, given the event B is true. Event B is also termed as **evidence**.
- $P(A)$ is the **priori** of A (the prior probability, i.e. Probability of event before evidence is seen). The evidence is an attribute value of an unknown instance (here, it is event B).
- $P(A|B)$ is a posteriori probability of B, i.e. probability of event after evidence is seen.

Now, with regards to our dataset, we can apply Bayes' theorem in following way:

$$P(y|X) = \frac{P(X|y)P(y)}{P(X)}$$

Where y is the class (0 to 9) and X is each independent feature.

Thereafter, class with the highest probability is assigned.
